

Cryptocurrencies Meet Equities: Risk Factors and Asset Pricing Relationships

Victoria Dobrynskaya[♦], Mikhail Dubrovskiy^{*}

June 2021

Abstract

We consider a variety of cryptocurrency and equity risk factors as potential forces that drive cryptocurrency returns and carry risk premiums. In a cross-section of 2,000 biggest cryptocurrencies, only downside market risk, cryptocurrency size and policy uncertainty factors are systematically priced with significant premiums. Momentum premium vanished in the recent years. Equity market risk appears to be more important than cryptocurrency market risk, suggesting greater linkages between cryptocurrency and equity markets than we used to think.

INTRODUCTION

Cryptocurrencies enter our lives and occupy portfolios of individual and institutional investors at tremendous pace (Bianchi and Babiak, 2021). Therefore, understanding which forces drive cryptocurrency returns is of great importance. Which risk factors are cryptocurrencies systematically exposed to? Which factors carry risk premiums? What are the linkages between cryptocurrency and traditional financial markets? This study is aimed to answer these questions.

Several recent studies have tried to impose factor structure on cryptocurrency returns. These studies can be divided into two groups. The first group explores how returns on a cryptocurrency market index or several major cryptocurrencies are related to various factors in *time-series* regressions. Milunovich (2018) documents significant Granger causality from equities, bonds and commodities to some cryptocurrencies. However, most studies find that major cryptocurrencies are not contemporaneously exposed to macroeconomic, equity or currency factors (Yermack, 2015; Corbet et al., 2018; Bianchi, 2020; Bianchi et al., 2020; Liu et al., 2020), and some coins only have a mild exposure to precious metals (Bianchi, 2020). Smales (2020) documents that Bitcoin is the main driving force for other big cryptocurrencies. Liu and Tsyvinski (2021) is the first comprehensive empirical study of a great number of factors which may potentially influence cryptocurrency returns over time. They find that the cryptocurrency market index is driven by cryptocurrency-specific factors, suggested in theoretical cryptocurrency pricing models (network factors, investor attention and time-series momentum), but has a weakly significant exposure to a stock market index and insignificant exposures to other equity factors, as well as precious metals, currency and macroeconomic factors, cryptocurrency value and cost-of-production factors.

The second group of studies considers cryptocurrency-specific factors in *cross-sectional* asset-pricing tests. Liu et al. (2020) and Liu et al. (2021) propose a three-factor model with cryptocurrency market, size and momentum factors, which are traded portfolios of cryptocurrencies themselves. The model explains cryptocurrency average returns well, and size and momentum factors carry significant premiums. Shen et al. (2020) document that a similar model with reversal factor instead of momentum is relevant for cryptocurrencies. Dobrynskaya (2020) demonstrates the importance of cryptocurrency downside market risk in addition to the aforementioned factors. Shanaev et al. (2019) propose cryptocurrency ‘age’ (period of listing) and ‘proof’ (proof-of-stake-minus-proof-of-work) factors to explain cryptocurrency returns. Assamoi and Ekponon (2020) is, to our knowledge, the only cross-sectional study of traditional market factors for cryptocurrencies, which shows ambiguous results. Only equity size and commodity factors are significantly priced, but with negative premiums,

and there is no monotonicity of returns in portfolio sorts by the factors. Unfortunately, the sample of this study is very narrow (100 biggest cryptocurrencies) in order to draw general conclusions.¹

We contribute to the second strand of cryptocurrency-related literature by running horse races between cryptocurrency-specific and traditional market factors in cross-sectional multifactor regressions for 2,000 cryptocurrencies with market capitalization above \$1 million. Even though some earlier studies document irrelevance of equity factors for the crypto-market index or several major cryptocurrencies, these factors may be significant drivers of other cryptocurrencies in a bigger sample, and may be compensated by risk premiums. So, we ask the question: Do equity factors explain cryptocurrency returns cross-sectionally in addition to cryptocurrency factors? Which risk factors are systematically priced and have high explanatory power in the cryptocurrency market?

Contrary to earlier studies, we find that equity market risk, particularly equity downside risk, is priced with a statistically significant premium, generalizing the findings of Dobrynska (2020) for the equity risk and a more recent time period. The equity market risk turns out to be even more important than the cryptocurrency market risk. This suggests greater linkages between cryptocurrency and equity markets in the recent years. However, we do not find evidence that other popular equity factors (size, value, momentum, volatility, profitability and investment) are priced in cryptocurrency market.

In line with previous findings, cryptocurrency-specific factors are priced with significant premiums, even after controlling for the equity market risk. Moreover, when we compare cryptocurrency factors to their counterparts for equities, we find that only cryptocurrency factors deliver statistically significant returns in the recent period 2014-2020, and the factors are uncorrelated with each other. However, contrary to Liu et al. (2020) and in line with Grobys and Sapkota (2019), we do not find evidence for either significant momentum effect, or significant momentum premium in the cryptocurrency market. The reason is extraordinary performance of several ‘past loser’ cryptocurrencies in the recent years.

Our study also contributes to the existing literature by documenting some explanatory power of two recently proposed cryptocurrency factors, which have not been tested cross-sectionally – volatility VCRIX (Kim et al., 2019) and uncertainty UCRY (Lucey et al., 2021). The both factors are priced with positive premiums, i.e. cryptocurrencies with greater exposure to volatility and uncertainty yield higher returns subsequently.

The uncertainty factor together with cryptocurrency size and equity downside risk factors form the best multifactor model for cryptocurrencies in term of explanatory power. However, these factors

¹ This study also has several methodological flaws (i.e. the assumption of constant betas and risk premiums) due to which the results may be biased.

do not explain *all* cryptocurrency returns since the intercepts remain positive and highly significant. Hence, the cryptocurrency market delivers high average returns which are still unexplained by the factors.

We also consider equity factors from different geographical regions and find that the global factors are the most relevant for the cryptocurrency market.

DATA

The period of study from January 10th, 2014 until October 30th, 2020 basically covers the whole history of the cryptocurrency market. Whereas Bitcoin was introduced in 2009, it remained the only cryptocurrency traded for several years, until a few other cryptocurrencies were introduced in early 2010s. However, we need a sufficient number of liquid cryptocurrencies to perform cross-sectional tests, hence we start our sample period in 2014, when the number of cryptocurrencies exceeds 20. Our sample period includes stable periods, booms and busts in the cryptocurrency market, so our results are not driven by a particular market trend.

We consider only "big" cryptocurrencies with the market capitalization above \$1 million. A cryptocurrency enters our sample when its capitalization exceeds this level, and may leave our sample if its capitalization drops subsequently. We also restrict the sample to cryptocurrencies with at least 27 weeks of uninterrupted observations. Overall, our sample includes 1986 such "big" cryptocurrencies traded over the seven years. Figure 1 depicts the growth of the number of cryptocurrencies in the sample from 22 in the beginning of our sample to about 1900 in the end.

We collect daily raw data on cryptocurrency prices and capitalizations from the usual source - coinmarketcap.com, which aggregates price data for each cryptocurrency from numerous exchanges. The data include delisted cryptocurrencies, so there is no concern about survivorship bias. We calculate weekly returns from Monday opening prices and Friday closing prices. Although cryptocurrencies are traded 7 days a week, we calculate the returns for working weeks in order to be comparable to equity weekly returns. So, we have 356 weeks of data and 216,369 return observations in total. The weekly frequency is chosen for several reasons. Firstly, there is less noise compared to daily frequency. Secondly, there is a sufficient number of time-series observations compared to monthly frequency. Due to the short history of the crypto-market (12 years) and the fast metabolism of cryptocurrencies, the weekly frequency seems to be optimal so far and it is used in many studies (e.g. Liu et al., 2020, Shen et al., 2020; Liu et al., 2021).

Cryptocurrency weekly returns have huge volatility and extreme observations, therefore, we winsorize the data by excluding 0.005% of outliers. Even after deleting outliers, the occasional weekly returns on single cryptocurrencies have been as small as -100% and as large as 12,439%.

We construct cryptocurrency market (CMKT), size (CSMB) and momentum (CWML) factors following the methodology of Liu et al. (2020). However, our factors are dated differently. Liu et al. (2020) consider the first 7 days of each year as the first week, the next 7 days as the second week and so on, whereas we use calendar weeks from Mondays to Fridays. The CMKT factor is the capitalization-weighted portfolio of all cryptocurrencies in our sample. The CSMB factor is a weekly rebalanced zero-cost portfolio, which has a long position in the 30% of the smallest cryptocurrencies and a short position in the 30% of the biggest cryptocurrencies, weighted by capitalizations. The CWML factor is a weekly rebalanced zero-cost portfolio, which has a long position in the 30% of cryptocurrencies with the highest previous-week returns and a short position in the 30% of cryptocurrencies with the lowest previous-week returns, weighted by capitalizations².

We collect a variety of equity factors from Kenneth French data library: the market (MKT), size (SMB), value (HML), investments (CMA), profitability (RMW) and momentum (WML) factors for the US, for four geographical regions (Asian-Pacific, North-American, European regions and Japan) and for the global market. Whenever a factor is not available at the weekly frequency, we use the daily data to calculate weekly returns, so that all factors are dated similarly.

We also collect the implied volatility factor for equities (VIX) from CBOE and a model-based forecast volatility factor for cryptocurrencies (VCRIX) from thecix.de, which was constructed by Kim et al. (2019) to capture the expectations of the cryptocurrency market volatility for the next 30 days in a similar way as VIX. Finally, we consider a cryptocurrency uncertainty factor (UCRY), which was recently proposed by Lucey et al. (2021). The data is retrieved from Brian Lucey website.

COMPARISON OF CRYPTOCURRENCY AND EQUITY MARKETS

First of all, we compare the cryptocurrency and equity markets in general. Table 1 reports the descriptive statistics for the US market factor (MKT), our CMKT factor, which represents the market portfolio of cryptocurrencies, and Bitcoin separately. Bitcoin is not only the oldest and biggest cryptocurrency, but is also the main “driving force” for other cryptocurrencies and the general market (Hu et al., 2019; Smales, 2020). Therefore, Bitcoin is often used as a proxy for the cryptocurrency market factor.

Compared to the equity market, the cryptocurrency market has about four times as high average and median returns and return volatility and a higher Sharpe ratio. The factor return dynamics are depicted on figure 2. Unlike the equity market, it has a positive skewness, so the

² Liu et al. (2020) construct the momentum factor based on the previous three-week returns; however, we use the one-week horizon because it generates the highest momentum in our sample period. Using longer sorting horizons does not affect our results significantly, but the momentum effect is less pronounced.

general market is more exposed to the jump risk, rather than the crash risk. Surprisingly, the crypto-market has a lower kurtosis.

Bitcoin and CMKT returns are highly correlated indeed (correlation 0.91), and both are weekly positively correlated with the equity market (correlation is only 0.11, but it is statistically significant). The equity market betas of CMKT and Bitcoin are rather high and significant (0.46 and 0.37, respectively), which is a consequence of their high volatility, rather than high correlation.³ The downside beta, which is conditional on the negative equity market returns, is significantly higher, than the regular beta, and the upside beta is close to zero. Therefore, the cryptocurrency market co-moves with the equity market much closer on the downside, when both are falling, but there is almost no systematic relationship between the markets on the upside. The cryptocurrency market has an insignificant exposure to equity size, value and momentum factors.

Size and momentum factors

Liu et al. (2020) consider a variety of cryptocurrency factors and show that only size and momentum factors have some systematic explanatory power for cryptocurrency returns. We look at these factors more closely and compare them with their sister factors for US the equity market. The factor descriptive statistics are reported in table 2 and the return dynamics are plotted on figure 2.

Whereas the size effect has been negligible in the equity market in the recent years (the average SMB return is -2% per annum in 2014-2020), it has been pronounced in the cryptocurrency market. The average annualized return on the CSMB factor is 61% and statistically significant, the factor has a Sharpe ratio of 12% and a positive skewness. As we can see on figure 2, there are many positive spikes in the CSMB returns, which are generated by occasional very high returns of small cryptocurrencies. The cryptocurrency and equity size factors are uncorrelated.

The cryptocurrency momentum (CWML) premium is rather high (46%), but statistically insignificant due to very high volatility. Similarly to Liu et al. (2021) and contrary to Shen et al. (2020), we observe short-term momentum effect rather than reversal. However, as we can see on figure 2, the factor has a few negative spikes, which were a consequence of extremely high occasional returns of a few cryptocurrencies, which turned out to be past losers. Deleting those observations would make the average momentum return higher and significant⁴. The equity momentum premium has been rather low (4%) and statistically insignificant in the recent years

³ Comparing global and regional equity market indices, the highest correlation and beta of CMKT are observed with respect to the European market (0.16 and 0.63, respectively) and the lowest correlation and beta are observed with respect to the Asian-Pacific region (0.08 and 0.35, respectively).

⁴ Since these negative spikes occurred in 2019-2020, the average momentum return was significantly higher in 2014-2018 – in the period of study of Liu et al. (2020), where they find that the momentum factor was significant in the cryptocurrency market.

similarly to the equity size premium. Both equity and cryptocurrency momentum factors have a negative skewness as an evidence of momentum crash risk (Daniel and Moskowitz, 2016). However, these crashes are unrelated and the two factors are uncorrelated.

Implied volatility factors

Since volatility is an important factor for any market, particularly for the cryptocurrency market, we compare the implied volatility factors VIX and VCRIX. The VCRIX factor was proposed by Kim et al. (2019) to measure the perceived future volatility of the cryptocurrency market in a similar way as VIX measures the perceived volatility of the US stock market. The authors use the Trimbora and Hardle's (2018) cryptocurrency market factor CRIX as a benchmark. CRIX has a varying over time number of constituents, which are determined econometrically by AIC to capture the movement of the cryptocurrency market. Because of the absence of developed derivatives market and impossibility of extracting implied volatility from derivatives prices (as in the case of VIX), Kim et al. (2019) developed a model to forecast the future volatility of CRIX and constructed the model-based implied volatility factor VCRIX.

Since VIX and VCRIX have different scales, we normalize VCRIX to have the same starting value as VIX on 5.12.2014 – the first date when VCRIX becomes available. The two volatility factors are plotted in the bottom panel of figure 2. The two factors are weakly positively correlated (statistically significant correlation 0.20) with many simultaneous spikes, which can be viewed as an evidence of volatility spillovers between the cryptocurrency and equity markets. The largest jump in implied volatilities in the both markets is observed at the outbreak of the Coronavirus pandemic in March 2020.

CRYPTOCURRENCY PRICING BY EQUITY AND CRYPTO FACTORS

In this section, we look at the whole cross-section of 1986 cryptocurrencies to investigate, which risk factors (cryptocurrency or equity), if any, explain their returns better. We start from the regular CAPM using MKT, CMKT and Bitcoin as different proxies for the market factor. Then we extend the model by adding downside risk, the Fama-French factors and implied volatility factors for the equity and cryptocurrency markets.

We employ the two step Fama-MacBeth procedure. On the first step, each cryptocurrency's returns are regressed on factors over a 26-week (half-year) horizon to estimated factor betas. On the second step, the cross-section of cryptocurrency returns in the subsequent week are regressed on their trailing betas to estimate risk premiums. Then the 26-week rolling window is moved by one week forward and the two steps repeat. And so on. The Fama-MacBeth methodology generates time

series of risk premiums and intercepts for each multifactor specification. The average risk premiums and their t-statistics are reported in table 3. Panel A reports alternative multifactor specifications using US equity factors as explanatory variables, and panel B reports specifications with cryptocurrency factors. A positive and statistically significant premium of a factor implies that cryptocurrencies which have higher exposures to this factor yield higher subsequent returns systematically. In other words, this factor is priced in the crypto-market.

The results in table 3 reveal that very few factors are priced systematically.

Specification 1 is the regular CAPM. The equity market factor carries a positive statistically significant premium of 13% per annum, whereas the cryptocurrency market premium of the same size is insignificant due to its high volatility⁵. However, when we control for the extra downside risk (specification 2⁶), we obtain statistically significant downside risk premiums for both MKT and CMKT (or Bitcoin), whereas the market premium becomes insignificant in all cases. This result confirms the findings of Dobrynskaya (2020), that downside risk is an important component in cryptocurrency pricing models. Whereas Dobrynskaya (2020) obtains this result with respect to the cryptocurrency market factor, we generalize it to the equity factor. The significance of the downside risk suggests that cryptocurrencies, which tend to correlate with the equity or cryptocurrency markets more when these markets are falling, are compensated by higher subsequent returns. The downside risk premium remains significant in all specifications where we control for other factors.

Specifications 3 and 4 in panel A are the 4-factor Carhart model (Carhart, 1997) and the 5-factor Fama-French model (Fama and French, 2015), respectively. We do not find any evidence of explanatory power of these equity factors for cryptocurrency returns. However, we do find a high explanatory power of the cryptocurrency size factor CSMB (specification 3 in panel B). Moreover, the cryptocurrency size and downside risk factors are both statistically significant in the 4-factor specification 4. The results confirm the findings of Dobrynskaya (2020) and Liu et al. (2021) with the exception of the cryptocurrency momentum factor. We find that the CWML factor generated negative returns in the recent years leading to insignificant whole-period average return and insignificant negative premium in the cross-sectional regressions.

Next, we observe a robust significant premium of 3% per annum for the UCRY Policy uncertainty factor (specifications 5-7 in panel B). Lucey et al. (2021) propose two uncertainty factors

⁵ All results are similar if we use Bitcoin instead of CMKT (not reported). The average Bitcoin premium (19%) is a little higher than the average CMKT premium (13%), but the time series of the both premiums are highly correlated with the coefficient of 0.91. Hence, using Bitcoin as a cryptocurrency market proxy is fully justified.

⁶ The CAPM with downside risk is proposed by Ang et al. (2006), tested empirically for different asset classes by Lettau et al. (2014) and for the cryptocurrency market by Dobrynskaya (2020). Compared to the CAPM, the model has an additional term – the relative downside risk premium, which is a compensation for the extra downside beta on top of the regular beta (β^-), where the downside beta is estimated in times when the market is falling.

for the cryptocurrency market: price uncertainty and policy uncertainty. They claim that informed investors would be sensitive to changes in policy uncertainty, whereas amateurs would be more responsive to price uncertainty. Hence, “it is important to distinguish between two types of cryptocurrency uncertainty, since it may help to better understand the behavior of different sets of investors in cryptocurrency markets” (Lucey et al., 2021). We find that only policy uncertainty is priced⁷. This is an indirect evidence of an important role of institutional investors in cryptocurrency markets. The uncertainty factor and the downside risk factor both remain significant in a three-factor specification 6. However, the uncertainty factor suppresses the significance of the size factor (specification 7).

Finally, we find weak evidence of a positive premium for volatility factors (VIX and VCRIX). Both VIX and VCRIX premiums are statistically significant at 90% confidence level (specification 6 in panel A and specification 8 in panel B), hence the both factors have similar explanatory power for the crypto-market.

On the next step, we run horse races between equity and cryptocurrency factors by putting them into regressions simultaneously (table 4). Since the factors from the two markets are uncorrelated, there is no problem with multicollinearity. Two major results follow. First, the equity market factor and, particularly, the equity downside risk factor are more important than the cryptocurrency market factors. The significance of cryptocurrency downside risk vanishes once we control for equity downside risk. Second, the cryptocurrency size and uncertainty factors remain significant once we control for equity factors. The explanatory power (R^2) of the model with equity downside risk, cryptocurrency size and uncertainty factors is the highest.

Overall, our results suggest that the cryptocurrency market has a weak (probably only emerging) factor structure, and the unexplained component of returns remains high, as evidenced by high and statistically significant intercepts and rather low R^2 . The cryptocurrency factors generally have a higher explanatory power than equity factors, which is not surprising given that the equity factors themselves have been insignificant in the recent years. The exception is the downside market risk factor, which has an equal explanatory power irrespective of whether we use the equity or the cryptocurrency market as the benchmark. Equity downside risk becomes even more important than cryptocurrency downside risk, when they are considered together. This suggests that the cryptocurrency market is somewhat integrated in the general financial market, and cryptocurrency investors hold diversified across markets portfolios. Then the equity index is a more relevant proxy for the market portfolio in line with our findings.

⁷ The estimates of risk premiums of the price uncertainty index are insignificant in all specifications and not reported.

CRYPTOCURRENCY PRICING BY GLOBAL AND REGIONAL FACTORS

The previous analysis was conducted with respect to the US equity market factors. However, since cryptocurrencies are traded globally 24/7, global or regional factors may be of greater relevance to explain cryptocurrency returns. Table 5 reports the Fama-MacBeth risk premiums in the 4-factor Carhart model with global and regional equity market factors in columns. Compared to the US factors (column 3 in panel A of table 3), the global factors have a little higher explanatory power indeed. The global market and momentum factors have significant premiums, whereas the SMB and HML factors are still insignificant. The regional factors perform worse than the global and US factors, and the weakest relationship is observed with respect to the Asian-Pacific market.

Interestingly, we observe significantly negative risk premiums for momentum factors in all markets. Given that our cryptocurrency momentum factor itself is also negatively correlated with the equity momentum factor, it seems that the timing of the momentum effect may be significantly different in the two markets and requires further investigation.

CONCLUSION

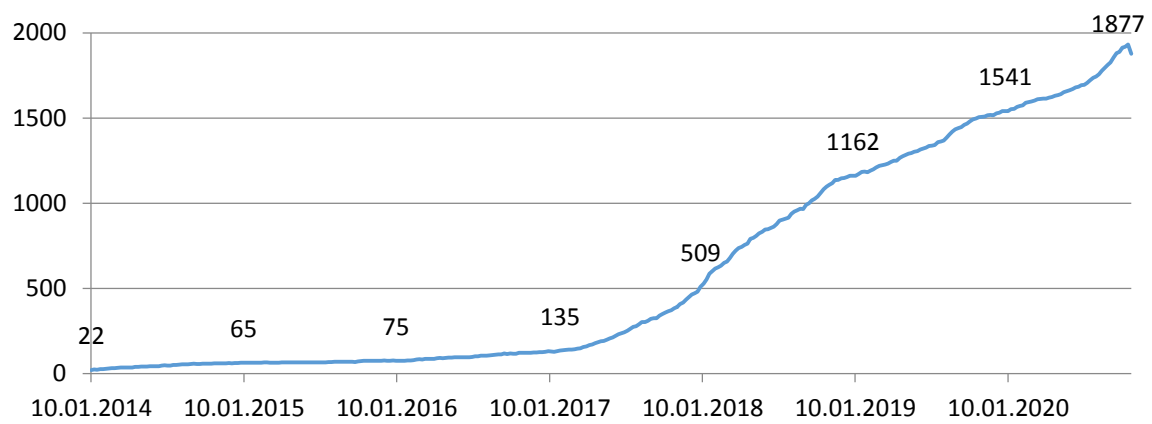

We run horse races between equity and cryptocurrency-specific risk factors in cross-sectional multifactor regressions for almost the whole cryptocurrency market. Equity downside risk, cryptocurrency size and uncertainty factors are the ones which are most consistently priced with positive premiums. A multifactor model with these factors has the highest explanatory power for cryptocurrency returns. Contrary to earlier studies, equity market risk appears even more important than cryptocurrency market risk, suggesting greater linkages between cryptocurrency and equity markets in the recent years. However, the factor structure of the crypto-market is only emerging, since the average unexplained crypto-market return remains high. We are likely to observe greater convergence of the markets and asset-pricing relationships in the future.

Figure 1. Number of cryptocurrencies with market capitalization above \$1 mln

The figure plots the total number of cryptocurrencies with market capitalization above \$1 million and at least 27 consecutive weekly observations. Sample period: January 2014 – October 2020.

Figure 2. Cryptocurrency and equity factors

The figure plots the dynamics of equity and cryptocurrency risk factors: the market (MKT, CMKT), size (SMB, CSMB), momentum (WML, CWML) and volatility (VIX, VCRIX). The market factors are capitalization-weighted indices of US stocks or cryptocurrencies, the size and momentum factors represent value-weighted long-short portfolios, sorted by capitalization or past returns.

Table 1. Comparison of equity and cryptocurrency market factors

	MKT	CMKT	Bitcoin
Mean annualized return	0.12 [1.84]	0.88 [3.41]	0.53 [2.11]
Median annualized return	0.20	0.73	0.55
Minimum weekly return	-0.15	-0.28	-0.31
Maximum weekly return	0.12	0.41	0.46
Standard deviation	1.22	4.86	4.73
Sharpe ratio	0.10	0.18	0.11
Skewness	-0.94	0.52	0.30
Kurtosis	8.95	2.41	2.83
Correlation (mkt, cmkt)	0.11 [2.17]		
Correlation (cmkt, Bitcoin)	0.91 [40.84]		
Stock market beta	1.00	0.46 [2.05]	0.37 [1.72]
Downside beta	1.00	0.62 [1.89]	0.67 [2.10]
Upside beta	1.00	0.25 [0.65]	0.04 [0.12]
SMB beta	0.38 [3.82]	0.26 [0.61]	0.47 [1.13]
HML beta	0.27 [3.04]	-0.12 [-0.33]	-0.01 [-0.04]
WML beta	-0.02 [-0.28]	0.06 [0.18]	0.18 [0.57]

The table reports return and risk characteristics of the US equity market factor, cryptocurrency market factor and Bitcoin. Betas with respect to equity risk factors (MKT, SMB, HML, WML) are estimated in the 4-factor Carhart model. T-statistics are reported in brackets.

Table 2. Comparison of equity and cryptocurrency size and momentum factors

	SMB	CSMB	WML	CWML
Mean annualized return	-0.02 [-0.52]	0.61 [2.26]	0.04 [0.76]	0.46 [0.95]
Median annualized return	-0.01	0.29	0.08	0.32
Minimum weekly return	-0.06	-0.23	-0.16	-1.21
Maximum weekly return	0.06	0.57	0.07	0.69
Standard deviation	0.64	5.12	1.09	9.21
Sharpe ratio	-0.03	0.12	0.04	0.05
Skewness	0.21	1.77	-1.36	-0.85
Kurtosis	2.71	7.06	9.76	9.43
Correlation	0.04 [0.78]		-0.05 [-0.85]	

The table reports return and risk characteristics of the US equity size (SMB) and momentum (WML) factors and cryptocurrency size (CSMB) and momentum (CWML) factors. The factors represent long-short portfolios, sorted by market capitalization and past returns, respectively. T-statistics are reported in brackets.

Table 3. Cross-sectional asset-pricing regressions with equity and cryptocurrency risk factors

The table reports the estimates of annualized premiums of equity (panel A) and cryptocurrency (panel B) risk factors, obtained in cross-sectional Fama-MacBeth regressions for up to 1,900 simultaneously traded cryptocurrencies. Alternative multifactor specifications are presented in columns. T-statistics are reported in brackets.

Table 4. Cross-sectional asset-pricing regressions with equity and cryptocurrency risk factors simultaneously

	1	2	3	4	5
Equity market	0.13 [1.97]	0.06 [0.87]	0.09 [1.52]	0.07 [1.16]	0.03 [0.56]

WML	-0.09 [-2.12]	-0.09 [-1.92]	-0.10 [-2.22]	-0.05 [-2.14]	-0.12 [-2.62]
Intercept	1.69 [5.35]	1.75 [5.53]	1.56 [5.04]	1.56 [5.03]	1.52 [5.03]
R ²	0.08	0.09	0.09	0.09	0.09

The table reports the estimates of annualized premiums of the 4-factor Carhart model, obtained in cross-sectional Fama-MacBeth regressions for up to 1,900 cryptocurrencies. Equity risk factors from 5 geographical regions are used in the alternative specifications in columns. T-statistics are reported in brackets.
